Objective: To examine the effects of oral creatine (Cr) monohydrate supplementation on muscle Cr concentration, body mass, and total body water (TBW), extracellular water (ECW), and intracellular water (ICW) volumes.

Design and Setting: After an overnight fast, urinary Cr and creatinine concentrations, muscle Cr concentration, body mass, TBW, ECW, and ICW were measured, and subjects were randomly assigned to either a Cr or a placebo (P) group. The Cr group ingested 25 g/d of Cr for 7 days (loading phase) and 5 g/d for the remaining 21 days (maintenance phase), whereas the P group ingested a sucrose P using the same protocol. All the measures were reassessed immediately after the loading and maintenance phases.

Subjects: Sixteen men (age = 22.8 ± 3.01 years, height = 179.8 ± 7.1 cm, body mass = 84.8 ± 11.2 kg) and 16 women (age = 21.8 ± 2.51 years, height = 163.4 ± 5.9 cm, body mass = 63.6 ± 14.0 kg) involved in resistance training volunteered to participate in this study.

Measurements: Muscle Cr concentration was determined from the vastus lateralis muscle using a percutaneous needle-biopsy technique. Total body water, ECW, and ICW volumes were assessed using deuterium oxide and sodium bromide dilution analyses.

Results: The Cr group experienced a significant increase in muscle Cr concentration, body mass, and TBW. The P group experienced a small but significant increase in TBW only.

Conclusions: The Cr supplementation protocol was effective for increasing muscle Cr concentrations, body mass, and TBW; however, fluid distribution was not changed.

Key Words: ergogenic aids, hydration, fluid balance, body mass, body composition

Creatine (Cr) supplementation continues to be extremely popular as a potential ergogenic aid among athletes at all levels. Studies have shown that muscle Cr and phosphocreatine can be significantly elevated when a normal diet is supplemented with Cr.1-4 The theory behind its use is similar to that of carbohydrate loading, because an increased muscle Cr content would conceivably enhance the capacity of the phosphagen energy system, providing greater resistance to fatigue and improving performance. Anecdotal reports of ergogenic value have been supported by scientifically conducted studies investigating its effects on strength,5-8 power,8-11 speed,12 and fatigue.4,13,14 However, not all the findings support ergogenic claims.3,15,16

Numerous anecdotal reports have associated muscle cramping, spasm, strains, gastrointestinal distress, kidney dysfunction, and heat illness with Cr supplementation. At this time, however, the only side effect directly associated with Cr supplementation is weight gain.5-8,11,13,16-19 Some of these authors have reported increases in body mass after only a loading phase of supplementation (20-25 g/d for 5-7 days).8,11,13,16 Thus, it is likely that the gains are due more to greater water retention during supplementation than to lean-tissue accretion. It is conceivable that increased muscle Cr concentrations are associated with changes in the intracellular osmotic pressure, resulting in movement of water into the cell, water retention, and weight gain. When water loss through sweating occurs from exercise, increased environmental temperatures, or a combination of both, this intracellular fluid shift may be detrimental. For example, the water bound inside the cell may not be available to the extracellular compartment for thermal regulation. Therefore, cramping and other heat-related problems may result from a fluid shift occurring during supple-
mentation. However, the existence of this Cr-related fluid shift is speculative because only 1 group to date has reported changes in fluid distribution after supplementation. It must be noted that fluid volumes were not measured directly in that study but were predicted using a bioelectric impedance analysis. Furthermore, muscle Cr was not assessed, so whether the changes in fluid distribution were actually associated with an increased muscle Cr concentration is unknown. Therefore, the purpose of this study was to investigate the effects of Cr supplementation on muscle Cr concentration and fluid distribution using a direct measure of fluid volumes.

METHODS

Subjects

Sixteen men (age = 22.8 ± 3.01 years, height = 179.8 ± 7.1 cm, body mass = 84.8 ± 11.2 kg) and 16 women (age = 21.8 ± 2.51 years, height = 163.4 ± 5.9 cm, body mass = 63.6 ± 14.0 kg) who were involved in a total-body resistance training program for at least 3 days per week were randomly assigned to either a Cr supplementation group or a placebo (P) group. We excluded subjects from participation if they had supplemented their habitual diet with any form of Cr during the past 60 days; were suffering from any form of kidney, liver, or endocrine disease or any disorder that might affect normal cellular levels of Cr or fluid balance (or both); or were taking any substance classified as a diuretic other than the caffeine found in their habitual diet. We also excluded women who were currently using oral contraceptives and women who had not completed 2 menstrual cycles since last using oral contraceptives. Before participating, each subject read a description of the study and signed an informed consent form approved by the university’s institutional review board, which also approved the study.

Procedures

The evening before the supplementation period began, each subject reported to the university’s General Clinical Research Center for an overnight stay and for baseline measurements. We instructed the subjects to refrain from any type of exercise after the last meal of the day before being admitted for the overnight stay. To control for changes in fluid distribution across the menstrual cycle, each woman began the study between days 1 and 7 of the cycle. Upon arrival at the Center, venous blood and urine samples were taken for a complete clinical chemistry panel (20 items) and for drugs of abuse, anabolic steroid, and pregnancy screen. After an overnight fast, we measured each subject for body mass, urinary Cr and creatinine concentrations, total body water (TBW) content, extracellular water (ECW) content, and muscle Cr concentration. Once these measurements were completed, the supplementation period began. We instructed the subjects to maintain their normal diets and their regular resistance-programming throughout the entire supplementation and testing period. We also instructed the subjects to refrain from ingesting any type of nonsteroidal anti-inflammatory medication, nutritional supplement, or substance classified as a diuretic other than the caffeine found in the habitual diet. Each subject was required to maintain a training log in which the number of sets, repetitions, and the resistance used were recorded during each exercise session. Additionally, we asked each subject to complete a weekly questionnaire designed to determine the incidence of any adverse effects during supplementation. All subjects reported back to the Center on the evening of the seventh and 28th (final) day of supplementation, at which time the overnight fast and subsequent measurements were repeated.

Supplementation

We randomly assigned each subject to either a Cr supplementation group or a P group in a double-blind fashion. Subjects in the Cr group (8 men, 8 women) ingested 5.0 g of Phosphagen (Experimental and Applied Sciences, Inc, Golden, CO) mixed with 15 g of a flavored simple carbohydrate 5 times per day for 7 days (loading phase). Immediately after the loading phase, each subject ingested the same supplement once a day for the remaining 21 days (maintenance phase). Subjects in the P group (8 men, 8 women) ingested 20 g of the flavored simple carbohydrate for 28 days using the same protocol as the Cr group. Individual-dose packages, identical in weight, were prepared for the Cr and the P groups and dispensed weekly. We instructed the subjects to mix the powder supplement with 16 oz (0.47 L) of water and maintain a daily record of the supplementation times. Finally, to further monitor compliance, we asked each subject to return any unused portions at the end of each week.

Measurements

Urinary Creatine and Creatinine. Urine samples were collected and frozen at −80°C for later analysis of Cr and creatinine concentrations using high-performance liquid chromatography.

Muscle Creatine Concentration. After local anesthesia and incision of the skin, muscle samples were obtained from the vastus lateralis muscle of the nondominant leg using a percutaneous needle-biopsy technique modified to include suction. Immediately after removal, the tissue samples were frozen in liquid nitrogen and stored at −80°C for later analysis. When all testing sessions were completed, the tissue samples were packaged in dry ice and shipped overnight to a human performance laboratory, where they were later freeze dried, dissected free of any blood and connective tissue, and powdered. The powdered muscle was then extracted with perchloric acid, neutralized, and analyzed enzymatically for muscle Cr using a spectrophotometric analysis described by Harris et al.

Body Mass and Total Body Water Volume. Body mass was assessed using a digital scale from the BOD POD Body Composition Tracking System (Life Measurements, Inc, Concord, CA). Total body water was determined using a deuterium oxide dilution method, which has been shown to be a valid and reliable measurement technique. We administered each subject an oral dose of deuterium oxide of approximately 0.15 g/kg of body mass, which was weighed out and diluted with sterile water for intake. Before ingestion and after a 4-hour equilibration period, two 5-mL venous blood samples were drawn for comparison. After extraction from the blood, the plasma was frozen at −20°C and stored for later analysis. Samples were then packaged with dry ice and shipped overnight to Metabolic Solutions, Inc (Nashua, NH), where deuterium enrichment in the body fluid was measured using isotope ratio mass spectrometry. The precision of this method is ±2%, and the percent coefficient of variation is typically

Journal of Athletic Training 45
The ECW compartment was determined using a sodium bro-
ologies Inc, San Diego, CA). This was performed as a backup
frequency bioelectrical impedance analyzer (Xitron Technol-
were observed in either group for blood or urine creatinine
concentrations. However, the time-by-group (F_{2,56} = 25.56,
P = .000) and time-by-sex (F_{2,56} = 4.04, P = .023) interac-
tions for urinary Cr concentration were significant. The Cr
group had significantly greater urinary Cr concentrations on
days 7 and 28 as compared with presupplementation, whereas
no changes were observed in the P group (Table). Furthermore,
women experienced greater urinary Cr concentrations than
did men on days 7 and 28.

Muscle Creatine Concentration

Assays for Cr could not be completed for 4 subjects (2 each
in the Cr and P groups); thus, these subjects were not included
in the Cr analysis. The time-by-group interaction was signi-
ficant (F_{2,48} = 4.75, P = .013); the Cr group had a greater Cr
contentration on days 7 and 28 as compared with presupple-
mentation (see Table). No changes were observed in the P
group. No differences were observed when the men and wom-
en within the Cr group were compared before or after supple-
mentation.

Body Mass

A significant time-by-group interaction (F_{2,56} = 3.30, P =
.044) was observed for body mass, as the Cr group experi-
cenced a significant increase from presupplementation to day
28 (see Table). The Cr group’s body mass on day 7 was 0.75
kg greater than at presupplementation; however, this change
was not significant. The Tukey post hoc test revealed that an
increase of 0.88 kg was necessary for statistical significance.
The P group did not experience any significant changes in
body mass. As expected, men had greater body mass than
women, but there were no significant sex interactions.

Total Body Water Volume

A significant time-by-group interaction (F_{2,56} = 3.86, P =
.027) was observed for TBW (see Table). Both groups ex-
perienced significantly greater TBW levels on days 7 and 28 as
compared with presupplementation, but the increase was greater
in the Cr group. The Tukey post hoc test revealed that a

0.75% daily.21 Total body water was calculated as the deute-
rium-dilution space divided by 1.04, which corrects for ex-
change of the deuterium with nonaqueous hydrogen of body
solids.21,22 We also assessed TBW using a Xitron 4200 multi-
frequency bioelectrical impedance analyzer (Xitron Technol-
gies Inc, San Diego, CA). This was performed as a backup
measure in case we were unable to perform the dilution anal-
ysis on the plasma samples.

Intracellular Water and Extracellular Water Volumes.
The ECW compartment was determined using a sodium bro-
mide dilution method.25–27 We administered each subject an
oral dose of sodium bromide (approximately 60 mg/kg of body
mass) simultaneously with the deuterium oxide solution. The
same blood samples taken for the deuterium analysis were also
used for the sodium bromide analysis, with the bromide con-
centration in the serum ultrafiltrate determined by high-per-
formance liquid chromatography (Metabolic Solutions, Inc). Be-
cause of the extreme sensitivity of this method, small quan-
tities of bromide can be administered for the analysis, allowing
for sufficient washout between measurement days.26 The cor-
corrected bromide space was calculated and used to determine the
ECW volume.25–27 The intracellular water (ICW) volume was
calculated by subtracting the ECW volume from the TBW
volume.

Statistical Analysis

We used the Statistical Package for the Social Sciences soft-
ware (version 10.0, SPSS Inc, Chicago, IL) to perform the
statistical analysis of the raw data. All dependent measures
were analyzed using a 1-within (time), 2-between (group and
sex) mixed design with repeated-measures analyses of vari-
ance and Tukey Honestly Significant Difference post hoc tests
to test differences between means. For all statistical tests, the
alpha level was set at .05.

RESULTS

Blood and Urine Analyses

Analyses for anabolic steroids and drugs of abuse were neg-
ative for all subjects at each testing date, and no differences

difference of 0.86 L was necessary for statistical significance. The differences of 0.87 and 0.89 L experienced by the P group were just higher than this value. Although no difference existed between the groups before supplementation, the Cr group had a significantly greater TBW volume on days 7 and 28 than did the P group. As expected, men had a greater TBW than women; however, there were no significant sex interactions.

**Extracellular Water and Intracellular Water Volumes**

As expected, men had greater ICW and ECW volumes, but there were no sex interactions. No other significant main effects or interactions, including a time-by-group interaction ($F_{2,56} = 1.02, P = .366$) for ICW, were observed. Furthermore, when ICW was expressed relative to the TBW, no significant changes were noted.

**DISCUSSION**

We examined the changes in muscle Cr, body mass, and body water during periods of Cr loading and maintenance in men and women. The supplementation protocol was indeed effective for increasing muscle Cr concentrations. The increases in muscle Cr were associated with increases in both TBW and body mass. However, only TBW increased during the loading phase, whereas the increase in body mass was not observed until both the loading and maintenance phases were completed.

**Muscle Creatine**

Several reports indicate that muscle Cr concentration can be elevated when a normal diet is supplemented with oral Cr. Our Cr group experienced a 20% increase in Cr concentration during the first week (loading phase) of supplementation. This increase was then maintained throughout the remaining 3 weeks (maintenance phase).

As expected, a large amount of between-subject variability was observed for the change in muscle Cr concentration from presupplementation to the end of the loading phase. Similar findings have been reported previously, which may explain why some individuals do not experience an ergogenic effect. Greenhaff reported that 20% to 30% of individuals do not respond to Cr supplementation (<10 mmol/kg dry mass [dm] [8%] in muscle Cr concentration). Similarly, we observed that 4 subjects (28%) in our study failed to respond to the supplementation. The dosages we used were not adjusted for body mass; thus, each subject ingested equal amounts of Cr. Because of this, it might be expected that a greater effect would be seen in individuals with smaller body mass. However, this was not observed because the nonresponders represented a wide range of body mass (57.09–86.21 kg). Furthermore, the increase experienced by women (body mass = 63.63 ± 12.58 kg) was not different from that experienced by men (body mass = 87.46 ± 11.98 kg). This is not unexpected because the 7-day loading protocol should have been sufficient for maximizing muscle uptake regardless of body mass. For example, women ingesting Cr experienced a greater increase in urinary Cr excretion than did men after both the loading and maintenance phases. Although sex differences have not been reported previously, they are not unexpected. Any Cr not taken in by the muscle or other tissues remains in the plasma and is eventually filtered through the kidneys and excreted in the urine. Because of their lower body mass, women had less available tissue for Cr uptake, resulting in a greater amount of excess Cr. Thus, factors other than the relative dose-response relationship play a role in the total Cr uptake by the muscle.

Greenhaff observed that 20% of individuals achieved Cr concentrations of approximately 150 to 160 mmol/kg dm after supplementation. This concentration is considered to be the upper limit of muscle Cr stores, although some individuals, including 4 subjects in the present study, achieve higher levels. Whereas a number of factors have been suggested to affect muscle Cr uptake, the primary determinant appears to be the initial muscle Cr concentration. The normal muscle Cr concentration of the human vastus lateralis appears to be approximately 124 mmol/kg dm. In our subjects, the average muscle Cr concentration before supplementation was 125.6 mmol/kg dm, with a large amount of between-subject variability (105.9–150.8 mmol/kg dm). Our findings are consistent with those of previous authors, who reported a wide variation (100–150 mmol/kg dm) in the initial muscle Cr content. Increases in muscle Cr concentration after supplementation appear to be inversely related to the initial Cr concentration.

In support of the above, we observed a significant correlation between the initial Cr levels and the increases in muscle Cr after supplementation ($r = -0.75, P < .01$). Subjects in the Cr group with an initial Cr concentration less than 120 mmol/kg dm experienced an average increase of 33.4 mmol/kg dm (23.1%), whereas subjects with an initial Cr concentration greater than 120 mmol/kg dm only experienced an average increase of 16.6 mmol/kg dm (11.2%) during the loading phase.

**Body Mass**

Previous investigators have reported increases in body mass after a loading phase of Cr supplementation. Although the Cr group did experience an increase in the present study, the increase did not reach significance until the entire supplementation protocol had been completed (1.31-kg increase after 28 days). In contrast, the P group failed to experience any significant changes in body mass. This is consistent with other studies reporting increases after a protocol of Cr loading and maintenance. However, body mass measurements were not taken immediately after the loading phase in those studies. Thus, whether their subjects experienced any immediate changes in body mass is unknown. In our study, the increase observed in the Cr group after the loading phase (0.75 kg) was slightly lower than what the Tukey post hoc test demonstrated as necessary for significance (0.88 kg). This was unexpected because increases of 0.70 and 0.75 kg after loading had previously been found to be statistically significant. However, our findings are not isolated because others have also failed to observe significant body mass changes after a loading phase of supplementation.

Although 4 subjects (including 3 women) in the Cr group failed to experience an increase in body mass after 28 days of supplementation, the range for those who did was consistent with gains previously observed, from 0.47 to 3.92 kg. At this time, the exact cause of the weight gain has not been determined. However, increases in protein synthesis and water retention are the 2 more commonly cited theories.

**Protein Synthesis.** It has been theorized that at least part of the increase in body mass can be attributed to increased
protein synthesis and morphologic changes within the skeletal muscle. Recently reported data suggest that Cr supplementation might amplify protein synthesis stimulation in response to resistance training. In that study, however, protein content was only examined after 12 weeks of supplementation and training. Thus, the effect of Cr after only 1 week or even after 4 weeks of training is unknown. As mentioned previously, because a number of authors reported increases in body mass in as few as 5 to 7 days, it is unlikely that these changes can be explained by protein synthesis alone.

Water Retention. The gains in body mass observed are likely due to water retention during supplementation. Creatine is an osmotically active substance. Thus, any increase in the body’s Cr content should result in increased water retention and consequent gains in body mass. For example, subject 1 in the present study, who reported having a fairly consistent body mass throughout the previous year, experienced a 4.8-kg increase in body mass during the first week of supplementation, 90% of which was accounted for by the increase in TBW. The limited number of investigators who have reported TBW volumes during supplementation provide contrasting results. Significant increases in TBW have been observed after 6 and 9 weeks of supplementation, whereas a similar 4-week protocol failed to affect TBW. However, whether the subjects in these studies actually experienced an increase in muscle Cr is unknown because Cr concentrations were not measured. Furthermore, in each of these studies, a bioelectric impedance analysis was used to estimate TBW. Such analysis is a prediction of TBW and is associated with errors ranging from 1.5 to 2.5 L. Dilution techniques, such as the deuterium oxide and sodium bromide we used, are considered criterion measures of body water. To our knowledge, we are the first to directly measure muscle Cr and fluid balance during supplementation, and our results suggest that increases in muscle Cr concentrations are associated with water retention. Both groups had similar TBW volumes at the beginning of the study. However, although both groups experienced an increase in TBW during the first week of supplementation, the Cr group’s TBW was significantly greater than the P group’s TBW after both the loading and maintenance phases (see Table). These findings support previous research because the increase experienced by the Cr group (4.86%) is similar to that observed using the bioelectric impedance analysis. We initially theorized that water retention would be responsible for the immediate gains in body mass after supplementation. As expected, the changes in TBW experienced by the Cr group were similar to those observed for body mass. The greatest increase in TBW (1.37 L) occurred during the first week of supplementation, whereas the greatest difference compared with presupplementation occurred after 28 days of supplementation (2.04 L). It is interesting to note, however, that the increase in TBW we observed would actually account for a greater increase in body mass. We would expect that a TBW increase of 1.37 L would be associated with a body mass increase of approximately 1.37 kg. Yet, the Cr group only experienced a nonsignificant 0.75-kg increase during this time. An explanation for this finding is not readily apparent but must involve decreased caloric intake or increased caloric expenditure (or both) during supplementation. A BOD POD Body Composition Tracking System digital scale was used for all body mass measurements, and a dilution technique was used to determine TBW. We also performed a bioelectric impedance analysis assessment of TBW as a secondary measure. When we analyzed these data, we observed a significant and identical 1.37-L increase in TBW after the loading phase. Thus, we do not question the validity of our data.

Fluid Intake. During the loading phase, the subjects in both groups ingested their respective supplements with approximately 454 mL of water 5 times per day. It is possible that the increase in TBW content is the result of an increased fluid intake during the week (~15.89 L). This is the most likely explanation for the slight increase experienced by the P group. However, the greater increase experienced by the Cr group suggests that the subjects experienced greater water retention. Thus, Cr uptake may have influenced water retention. Because fluid intake and urinary volume were not assessed, we could not determine whether increased fluid intake or decreased fluid loss or both were responsible for the change in body water.

Caloric Intake and Expenditure. We instructed our subjects to maintain their normal, habitual diet throughout the supplementation period. Although we did not record dietary intake, other authors have reported consistent caloric intakes while increases in body mass occurred during supplementation. Anecdotally, our subjects reported a decreased appetite at times during the supplementation period because they described a “full” feeling from ingesting the supplement and fluid on 5 occasions each day. Decreases in caloric intake during supplementation have been previously reported. Unfortunately, TBW volumes were not assessed in these studies; thus, it is unknown if they increased or not. It is also possible that the subjects in the Cr group experienced an ergogenic effect, allowing for greater training volume during this period. This may have resulted in greater caloric expenditure. Thus, it is possible that increased fluid intake, decreased caloric intake, and increased caloric expenditure are responsible for our findings.

Intracellular Water Retention. Because Cr is primarily stored intramuscularly (95%), it is more likely that the increase in TBW would be intracellular because of the direct influx of water into the muscle cell. Previous investigators were unable to determine whether increases in lean body mass were due to cellular water retention or gains in actual muscle protein, because only TBW was assessed during supplementation. More recently, however, fluid distribution has been assessed but only using the bioelectric impedance analysis. We directly measured fluid distribution using dilution techniques and observed a 11.3 L (4.62%) increase in ICW in the Cr group. However, this change was not statistically significant. Increases in ICW have been reported previously using the bioelectric impedance analysis. In those studies, increases of 3.30 L (9.0%) and 1.00 L (4.93%) were statistically significant.

The nonsignificant increase we observed accounted for 55.4% of the increase in TBW volume, which is fairly consistent with normal fluid distribution (approximately two thirds of the TBW is intracellular). This suggests an equal distribution of fluid during supplementation. Interestingly, an increase in cell volume appears to be an anabolic proliferative signal, which may be the first step in muscle protein synthesis. Because of this, increased cell volume has been suggested as a mechanism for protein synthesis stimulation and increased muscle mass under conditions of muscular overload during Cr supplementation.
Adverse Effects

None of the blood or urinary measures suggested any adverse effects as a result of supplementation. Furthermore, none of the subjects in the present investigation experienced muscle cramping or any other side effects (other than increased body mass) during the supplementation protocol. However, whether any subjects performed exercise bouts resulting in a large amount of water loss is unknown. Thus, a potential relationship between Cr supplementation and heat illness cannot be established from the results of the present investigation.

Limitations of the Study

As mentioned previously, caloric and fluid intakes were not recorded, and differences in either of these factors could have influenced the changes in body mass and fluid balance. Furthermore, each subject was involved in an individualized resistance training program. These training protocols were not controlled for; however, the volume of each training session was recorded. Because of a large amount of variability across subjects, a relationship between training volume and changes in body mass and fluid balance could not be established. Furthermore, training protocols before supplementation were not recorded, so comparisons could not be made. Thus, it is possible that the differences in training volume may also have influenced the changes in body mass and fluid balance.6,38,39

CONCLUSIONS

Our results indicate that the supplementation protocol was effective in increasing muscle Cr concentrations. Increased muscle Cr content was associated with an increased body mass and TBW volume. Thus, supplementation does result in water retention. It was initially hypothesized that the water would be preferentially retained intracellularly, altering fluid distribution. However, this was not observed. Therefore, the theory of a Cr-related fluid shift is not supported because fluid distribution remained normal. An alteration in fluid distribution during supplementation had been suggested as a cause of muscle cramping and other heat-related problems anecdotally associated with Cr supplementation. Because the subjects failed to experience any side effects beyond weight gain, it cannot be determined whether athletes supplementing their habitual diet with oral Cr monohydrate will be more predisposed to muscle cramping and heat illness than athletes who are not ingesting Cr. However, our results do not support the fluid-shift theory behind Cr supplementation and heat illness. Thus, from this investigation, a potential relationship between Cr supplementation and heat illness cannot be established. It will be of value for future researchers to focus on changes in fluid balance and the occurrence of heat illness when Cr supplementation is combined with fluid loss during exercise.

ACKNOWLEDGMENTS

This work was supported in part by a grant from the National Athletic Trainers’ Association Research and Education Foundation and in part by a grant from the National Institutes of Health to the University of Virginia, General Clinical Research Center, M01 RR08487. We thank Dr Lori Wideman, Dr Judy Weltman, Sandra Jackson, RN, and the University of Virginia General Clinical Research Center staff for their assistance during the data collection. We also thank Experimental and Applied Sciences (EAS) Inc, Golden, CO, for supplying the Cr monohydrate used in the investigation.
