Food ingestion in an upright sitting position increases postprandial amino acid availability when compared with food ingestion in a lying down position

Andrew M. Holwerda, Kaatje Lenaerts, Jörgen Bierau, Will K.W.H. Wodzig, and Luc J.C. van Loon

Abstract: Dietary protein digestion and absorption kinetics determine the postprandial increase in muscle protein synthesis. We recently demonstrated that body position during feeding can modulate the postprandial rise in plasma amino acid availability. Here we investigated whether protein ingestion in an upright sitting body position accelerates gastric emptying and improves dietary protein digestion and subsequent amino acid absorption compared with feeding in a supine lying body position. In a crossover design, 8 young males (age, 26 ± 1 years; body mass index, 24.0 ± 0.9 kg·m⁻²) ingested 20 g intrinsically L-[¹³C]-phenylalanine–labeled milk protein plus 1.5 g paracetamol while sitting in an upright position or lying down in a supine position. Blood samples were collected frequently during a 5-h postprandial period. Gastric emptying rates and dietary protein digestion and absorption were assessed using plasma paracetamol and amino acid concentrations as well as plasma L-[¹³C]-phenylalanine enrichments. Peak plasma leucine concentrations were higher when protein was ingested in an upright sitting versus lying position (213 ± 15 vs 193 ± 12 μmol·L⁻¹, P < 0.05), which was accompanied by a trend for a greater overall leucine response (13 989 ± 720 vs 11 875 ± 1073 AU, respectively; P = 0.05). Peak plasma paracetamol concentrations were higher in the sitting versus lying treatment (11.6 ± 0.5 vs 9.3 ± 0.6 mg·L⁻¹, P < 0.05). Protein ingestion in an upright sitting position accelerates gastric emptying and increases the postprandial rise in plasma amino acid availability by increasing protein digestion and amino acid absorption rates. Therefore, feeding in an upright body position as opposed to a lying position is an important prerequisite to allow proper postprandial muscle protein accretion.

Key words: protein, digestion, gastric emptying, body position, amino acids, leucine, postprandial.

Résumé : La digestion des protéines alimentaires et la cinétique de l’absorption déterminent l’augmentation postprandiale de la synthèse des protéines musculaires. Nous avons récemment démontré que la position du corps durant le processus de l’alimentation pouvait moduler l’augmentation postprandiale de la disponibilité des acides aminés dans le plasma. Dans la présente étude, nous examinerons si, en position assise, tronc à la verticale, l’ingestion de protéines accélère la vidange gastrique, améliore la digestion des protéines alimentaires et l’absorption postprandiale des acides aminés comparativement à l’alimentation en position couchée à l’horizontale. Selon un devis croisé, huit jeunes hommes (âge, 26 ± 1 ans, indice de masse corporelle, 24.0 ± 0.9 kg·m⁻²) ingèrent 20 g de protéines de lait intrinsèquement marquées à la L-[¹³C]-phénylalanine plus 1.5 g de paracétamol en position assise, tronc à la verticale, ou en position couchée, tronc à l’horizontale. On préleve plusieurs échantillons de sang durant les 5 heures de la période postprandiale. On évalue la vidange gastrique, la digestion et l’absorption des protéines alimentaires au moyen des concentrations plasmatiques de paracétamol et d’acides aminés et de l’enrichissement du plasma en L-[¹³C]-phénylalanine. La concentration plasmatique de pointe de la leucine est plus élevée quand les protéines sont ingérées en position assise, tronc à la verticale comparativement à la position couchée (213 ± 15 vs 193 ± 12 μmol·L⁻¹, P < 0.05); ce phénomène est accompagné d’une tendance à une plus grande réponse globale de la leucine (13989 ± 720 vs 11875 ± 1073 AU, respectivement; P = 0.05). La concentration plasmatique de pointe de paracétamol est plus élevée dans la position assise comparativement à la position couchée (11.6 ± 0.5 vs 9.3 ± 0.6 mg·L⁻¹, P < 0.05). L’ingestion de protéines en position assise, tronc à la verticale, accélère la vidange gastrique et amplifie la disponibilité plasmatique des acides aminés en accroissant la digestion des protéines et le taux d’absorption des acides aminés. Par conséquent, l’alimentation en position debout comparativement à la position couchée est un prérequis important pour favoriser l’accrétion adéquate des protéines musculaires durant la période postprandiale.

Mots-clés: protéines, digestion, vidange gastrique, position corporelle, acides aminés, leucine, postprandial.

Introduction

Protein ingestion increases muscle protein synthesis rates (Yang et al. 2012a, 2012b; Burd et al. 2015). The postprandial increase in muscle protein synthesis rate has been attributed to the rise in circulating (essential) amino acid concentrations, with the postprandial rise in circulating plasma leucine concentrations being of particular relevance (Dreyer et al. 2008; Wall et al. 2013). Regulation of the postprandial muscle protein synthetic response...
occurs on multiple levels, ranging from protein digestion and amino acid absorption (Koopman et al. 2009), postprandial insulin release and subsequent muscle perfusion (Rasmussen et al. 2006), amino acid uptake in muscle (Dickinson et al. 2013), activation of anabolic signaling pathways (Fry et al. 2011), and subsequent myofibrillar protein synthesis (Yang et al. 2012a, 2012b; Burd et al. 2015). Differences in the anabolic properties of various proteins have been attributed to their amino acid composition (Churchward-Venne et al. 2012) as well as their specific protein digestion and amino acid absorption kinetics (Calbet and Holst 2004).

The postprandial muscle protein synthetic response to feeding is influenced by various factors that may modulate postprandial protein digestion and amino acid absorption (Dangin et al. 2001; Koopman et al. 2009; Pennings et al. 2011). For example, the postprandial stimulation of muscle protein synthesis can be influenced by the type of protein (Dangin et al. 2001; Pennings et al. 2011), the matrix in which the protein is consumed (Soop et al. 2012; Churchward-Venne et al. 2015), the macronutrient composition of a protein rich meal (Gorissen et al. 2014), as well as actual food preparation procedures (Bax et al. 2012; Pennings et al. 2013) and mastication (Rémond et al. 2007). We recently identified body position during and/or after feeding as an important factor influencing the postprandial muscle protein synthetic response. We demonstrated that ingesting 22 g protein in a head-down tilted body position slows down gastric emptying rate and substantially lowers postprandial plasma amino acid availability when compared with the ingestion of the same amount of protein in a proper upright sitting body position (Holwerda et al. 2016).

Based upon these proof-of-principle findings, we hypothesized that food intake in an upright sitting position results in more rapid gastric emptying, thereby accelerating protein digestion and subsequent amino acid absorption when compared with feeding in a lying position. Understanding the impact of body position on protein digestion and absorption is of important clinical relevance as many patients in the hospital remain in a lying position during and/or after feeding. Based upon our hypothesis, feeding in a lying body position could impair postprandial protein handling and, as such, contribute to the development of anabolic resistance during bed rest following injury or disease.

To test our hypothesis that postprandial protein handling differs when protein is ingested in an upright sitting versus lying down position, we selected a group of males who were subjected to 2 experiments where gastric emptying rate and protein digestion were assessed after consuming 20 g protein in an upright sitting versus lying down position. To simultaneously assess gastric emptying rates and protein digestion and amino acid absorption, subjects were administered 20 g intrinsically L-[1-13C]-phenylalanine–labeled milk protein (van Loon et al. 2009) mixed with 1.5 g paracetamol powder (acetaminophen, Kruiviat, Leiden, the Netherlands) once while sitting in an upright body position and once while lying in a supine horizontal body position. Subjects remained in the respective body position for the duration of each trial (330 min total). Each trial was separated by a minimum of 6 days. Subjects ingested the test drink through a spout of a sports drink bottle to prevent any spillage. Drink ingestion time in both treatment positions was standardized to 5 min. The provision of paracetamol in combination with repeated blood sampling over a 5-h postprandial period allowed for assessment of gastric emptying rate (see below for methodological description). The provision of intrinsically L-[1-13C]-phenylalanine–labeled protein combined with repeated blood sampling over a 5-h postprandial period allows assessment of dietary protein digestion and amino acid absorption. Upon ingestion and subsequent digestion of the intrinsically L-[1-13C]-phenylalanine–labeled protein, increases in L-[1-13C]-phenylalanine enrichment in the circulation provide a reference measurement for protein digestion and subsequent absorption of dietary protein-derived amino acids.

Materials and methods

Subjects

Eight healthy young subjects (age, 26 ± 1 years; body mass index (BMI), 24.0 ± 0.9 kg·m−2) participated in this randomized, cross-over trial. Subjects were included if they were between the ages of 18 and 35 years with a BMI between 18 and 30 kg·m−2. Potential subjects were excluded if they reported gastrointestinal dysfunction/disease (lactose intolerance, celiac disease) or if they were taking any form of medication that could impair gastrointestinal function. All participants were informed about the purpose of the study, experimental procedures, and possible risks prior to providing written consent to participate. This study was approved by the Medical Ethical Committee of the Maastricht University Medical Centre, the Netherlands (METC 14-3-052), and conformed to standards for the use of human subjects in research as outlined in the seventh revision of the Declaration of Helsinki (Brazil, 2013). All participants provided written informed consent before participation. This study was registered at the Netherlands Trial Register (http://www.trialregister.nl) as NTR5027.

Diet and physical activity before testing

All subjects were instructed to keep their diet consistent, to refrain from alcohol consumption, and to refrain from performing any exhaustive physical activity for 2 days before each test day. Subjects reported to the lab for each test day under resting and fasted conditions, having not eaten anything from 2200 h the night before testing.

Experimental procedure

According to the randomized, cross-over study design, each subject ingested 20 g L-[1-13C]-phenylalanine–labeled milk protein (MPC80) mixed with 1.5 g paracetamol powder (acetaminophen, Kruiviat, Leiden, the Netherlands) once while sitting in an upright body position and once while lying in a supine horizontal body position. Subjects remained in the respective body position for the duration of each trial (330 min total). Each trial was separated by a minimum of 6 days. Subjects ingested the test drink through a spout of a sports drink bottle to prevent any spillage. Drink ingestion time in both treatment positions was standardized to 5 min. The provision of paracetamol in combination with repeated blood sampling over a 5-h postprandial period allowed for assessment of gastric emptying rate (see below for methodological description). The provision of intrinsically L-[1-13C]-phenylalanine–labeled protein combined with repeated blood sampling over a 5-h postprandial period allows assessment of dietary protein digestion and amino acid absorption. Upon ingestion and subsequent digestion of the intrinsically L-[1-13C]-phenylalanine–labeled protein, increases in L-[1-13C]-phenylalanine enrichment in the circulation provide a reference measurement for protein digestion and subsequent absorption of dietary protein-derived amino acids.

Testing protocol

After an overnight fast, a polyurethane catheter was placed in the antecubetal vein of the elbow for frequent blood sampling. At t = −30 min, a basal blood sample was collected from the catheter and blood pressure and heart rate was measured once at the upper arm and once at the ankle. After baseline measurements, subjects positioned themselves in either the sitting or supine position based on randomization. While in the seated position, subjects sat in a standardized, stationary chair with arm rests and were instructed to hold their lower back against the back support of the chair. Subjects were supervised throughout the test day and were constantly reminded to maintain the upright posture. For the lying treatment, subjects were laid in a standard hospital bed and were instructed to lay supine for the duration of the trial. Subjects were given a pillow to rest their heads, which was positioned so that the upper back would remain in contact with the bed. After subjects were positioned in the respective body positions of each treatment, they acclimatized for 30 min, after which another blood sample was collected and blood pressure and heart rate were measured (t = 0 min). Following these measurements, the test drink was ingested, signifying the start of the 300-min postprandial period. Venous blood samples were collected at t = 15, 30, 45, 60, 90, 120, 180, 240, and 300 min. Blood samples were collected in EDTA-containing tubes and centrifuged at 1000 g for 10 min at 4 °C. Aliquots of plasma were frozen in liquid nitrogen and stored at −80 °C. Blood pressure and heart rate was measured at the upper arm and ankle at t = 60, 120, 180, 240, and 300 min.
Preparation of study beverage
Subjects ingested 20 g intrinsically L-[1-13C]-phenylalanine–labeled milk protein (MPC80) with an added 1.5 g paracetamol powder dissolved in water up to 500 mL. We chose to use intrinsically labeled milk as opposed to either rapid or more slowly digestible whey or micellar casein fractions (Dangin et al. 2001; Koopman et al. 2009), as milk- and milk protein-based products are generally part of our diets. The intrinsically L-[1-13C]-phenylalanine–labeled milk protein was obtained by infusing a Holstein cow with large quantities of L-[1-13C]-phenylalanine, collecting the milk, and purifying the milk protein fraction as described previously (van Loon et al. 2009). The L-[1-13C]-phenylalanine enrichment of the intact MPC80 was 7.7 mole percent excess (MPE). The MPC80 met all chemical and bacteriologic specifications for human consumption.

Gastric emptying
Gastric emptying was assessed by measuring the postprandial rise in plasma paracetamol (acetaminophen) concentrations after ingestion of protein with 1.5 g paracetamol added (Glerup et al. 2007). With paracetamol being rapidly absorbed in the small intestine, gastric emptying forms the rate-limiting step determining the appearance rate of paracetamol in the circulation. Peak plasma paracetamol concentrations are typically reached after 30–60 min following ingestion with a half-life of ~2 h (van Can et al. 2014). We used plasma paracetamol appearance in the circulation as a marker of gastric emptying as applied previously in our laboratory (van Can et al. 2014; Holwerda et al. 2016) as well as others (Horowitz et al. 2012; Panahi et al. 2014).

Plasma analysis
Plasma glucose and insulin concentrations were analyzed using commercially available kits (Glucose HK CP, Horiba ABX Diagnostics, France; Ref: AA11A01667; and Human Insulin-specific (radioimmunoassay), Merck Millipore, Germany, cat. no. HI-14K, respectively). Plasma (100 μL) for amino acid analyses was deproteinized on ice with 5-sulphosalicylic acid, mixed, and the clear supernatant was collected after centrifugation. Amino acid profiles were determined using ultra-performance liquid chromatography tandem mass spectrometry as described previously (Waterfall et al. 2009). Plasma leucine concentrations were analyzed with an acetylamphen assay kit (K991598, Roche, Basel, Switzerland) with the COBAS-Integra 800 immuno-assay analyzer. Briefly, acetylamphen was hydrolyzed to p-aminophenol and acetate. The p-aminophenol was then converted to an indophenol by enzymatic reaction. The production of indophenol was colorimetrically analyzed and was directly proportional to acetylamphen concentration in plasma.

Statistical analysis
The study was powered according to an anticipated difference in plasma leucine peak concentrations. Based on previously published data (Pennings et al. 2011; Holwerda et al. 2016), we expected the mean effect difference in peak plasma leucine concentrations to be approximately 30 μmol·L⁻¹ and the standard deviation to be 25 μmol·L⁻¹. A sample size of 8 subjects was calculated using a power of 80% (1−β = 0.8) and a 2-sided significance level of 5% (α = 0.05). All data are expressed as means ± SE. Time-dependent variables (i.e., plasma glucose and insulin concentrations, plasma amino acid concentrations, plasma L-[1-13C]-phenylalanine enrichments, and plasma paracetamol concentrations) were analyzed by 2-factor repeated-measures ANOVA. The analysis was carried out for the period starting at the time of protein ingestion, between t = 0 and 300 min. Upon identification of a significant interaction, Bonferroni post hoc testing was used to identify time points in which the treatments were different. Differences in treatment-dependent variables, such as area under the curve (AUC), were analyzed using Student’s paired t test. Pearson’s r product moment correlation was used to examine the linear relationship between plasma leucine amino acid and paracetamol concentrations after protein ingestion while seated (upright; n = 8) and while lying in a supine body position (lying down; n = 8). The data were analyzed with a 2-way repeated-measures (treatment × time) ANOVA. Glucose − time effect: P < 0.05; time × treatment interaction: P < 0.01. Insulin − time effect: P < 0.01; time × treatment interaction: P < 0.05.

Results
Plasma glucose and insulin
Plasma glucose concentrations (Fig. 1A) decreased slightly following protein intake in both treatments (time effect, P < 0.01). Plasma insulin concentrations (Fig. 1B) increased following protein ingestion in both treatments (time effect, P < 0.01). The changes in plasma glucose and insulin concentrations were different between the sitting and lying treatments (time × treatment interaction, P < 0.05). Peak postprandial insulin concentrations were reached at t = 15 min and tended to be lower in the lying versus sitting treatment (20 ± 5 vs 25 ± 3 mU·L⁻¹, P = 0.09).

Plasma amino acid responses
Plasma leucine (Fig. 2A), total essential (Fig. 2B), and total non-essential (Fig. 2C) amino acid concentrations increased following protein ingestion in both treatments compared with baseline (P < 0.01). Plasma leucine and total essential amino acid concentrations showed an attenuated rise in the lying compared with the sitting treatment (time × treatment, P < 0.05), with concentrations being significantly lower between t = 30–45 min in the lying compared with sitting position (P < 0.05). Overall plasma leucine availability, assessed using AUC analysis over 300 min, tended to be lower in the lying compared with sitting treatment (P = 0.09). No significant differences in overall plasma essential and nonessential availability over 300 min were observed after protein ingestion between treatments (P > 0.05). After protein ingestion,
plasma L-[1-13C]-phenylalanine enrichments (Fig. 3), originating from the ingested protein, increased rapidly in both treatments reaching maximal values of 2.0 ± 0.2 MPE at $t = 30$ min in the sitting treatment and 1.9 ± 0.1 MPE at $t = 60$ min in the supine lying treatment (main effect for time, $P<0.01$; time × treatment interaction, $P<0.01$). Area under the curve over 300 min (arbitrary units, AU) inset and analyzed with a Student’s paired t test. *, Significant differences ($P<0.05$) between treatments within each time point. †, Trend for a difference between treatments ($P<0.10$).

Gastric emptying

Plasma paracetamol concentrations (Fig. 4) increased following protein ingestion in both treatments ($P<0.05$). Peak paracetamol concentrations reached 11.2 ± 0.8 mg·L$^{-1}$ at $t = 45$ min in the sitting treatment and 9.3 ± 0.6 mg·L$^{-1}$ at $t = 90$ min ($P<0.05$) in the supine lying treatment. Gastric emptying during the early postprandial phase, assessed by paracetamol AUC between $t = 0–60$ min was 23% ± 7% lower in the lying compared with sitting treatment (521 ± 45 vs 395 ± 42 AU; $P<0.01$). When assessed over the entire 300-min postprandial period, paracetamol AUC no longer differed between treatments ($P>0.05$).

Discussion

In the present study, we observed that gastric emptying rate was accelerated when protein was ingested in an upright sitting versus supine-lying body position. The postprandial rise in circu-
lating leucine concentrations was greater when protein was ingested in the upright sitting position, which was accompanied by a trend for greater overall plasma leucine availability when compared with the lying position.

The postprandial rise in plasma essential amino acids, and leucine in particular, is a key factor for driving the stimulation of postprandial muscle protein synthesis (Dreyer et al. 2008; Wall et al. 2013). In the present study, ingestion of a meal-like amount of protein rapidly increased plasma insulin (Fig. 1B), essential amino acids (Fig. 2B), and leucine (Fig. 2A) concentrations. The postprandial rise in plasma amino acid availability was attributed to the appearance of dietary protein-derived amino acids in the circulation, as evidenced by the postprandial rise in both plasma phenylalanine concentration and $\delta$-[1-13C]-phenylalanine enrichments (Fig. 3). When protein was ingested in the sitting position, plasma essential amino acid concentrations reached peak levels of $1277 \pm 69 \mu$mol·L$^{-1}$, with plasma leucine concentrations reaching $223 \pm 14 \mu$mol·L$^{-1}$. Such postprandial increases in plasma essential amino acid concentrations, and plasma leucine in particular, have previously been shown to increase muscle protein synthesis rates by 30%–100% when compared with basal, postabsorptive muscle protein synthesis rates (Yang et al. 2012a; 2012b; Gorissen et al. 2014; Burd et al. 2015; Churchward-Venne et al. 2015).

The same, meal-like amount of protein ingested in the lying down position resulted in a blunted postprandial rise in plasma insulin (Fig. 1B), total essential amino acids (Fig. 2B), and leucine (Fig. 2A) concentrations when compared with protein intake in an upright sitting position. After protein ingestion in the lying down position, peak plasma leucine concentration reached $193 \pm 12 \mu$mol·L$^{-1}$, which was significantly lower when compared with postprandial peak plasma leucine concentrations observed following protein ingestion in a seated position. In accordance, plasma leucine availability over the entire 5-h postprandial period was 15% ± 6% less following protein ingestion in the lying versus upright, seated position ($P = 0.05$). The attenuated rise in postprandial plasma leucine availability observed between the upright sitting and lying down positions is in line with previous proof-of-principle data from our lab comparing plasma amino acid availability after protein ingestion in an upright sitting versus head-tilted-down body position (Holwerda et al. 2016). The blunted postprandial rise in plasma leucine and total essential amino acid concentrations after protein ingestion in a lying down position would unlikely suffice to induce a measurable postprandial increase in muscle protein synthesis rates as demonstrated in previous work (Yang et al. 2012a, 2012b).

The modulation of postprandial plasma leucine availability has also been demonstrated in various studies assessing protein digestion and absorption kinetics and muscle protein synthesis rates after ingestion of different protein amounts (Yang et al. 2012a, 2012b; Pennings et al. 2012), types (Koopman et al. 2009; Pennings et al. 2011), and meals with different macronutrient compositions (Gorissen et al. 2014). By combining the ingestion of intrinsically $\delta$-[1-13C]-phenylalanine–labeled protein with the continuous intravenous $\delta$-[ring-2H5]-phenylalanine infusion, some of these studies were able to demonstrate that a greater first-pass splanchnic extraction of dietary protein-derived amino acids was likely responsible for the attenuated postprandial rise in plasma amino acid availability (Koopman et al. 2009; Pennings et al. 2011; Gorissen et al. 2014). In the present study, we provided our subjects with intrinsically $\delta$-[1-13C]-phenylalanine–labeled protein. By collecting blood samples over a 5-h postprandial period and measuring both plasma phenylalanine concentrations as well as $\delta$-[1-13C]-phenylalanine enrichments, we were able to compare the postprandial rise in dietary protein-derived amino acid availability in the circulation, providing insight into dietary protein digestion and amino acid absorption kinetics (van Loon et al. 2009). We observed a modulation in the temporal pattern of dietary protein-derived amino acid availability with protein ingestion in the sit-

ting as opposed to lying position, resulting in a more rapid release of dietary protein-derived amino acids without changing overall plasma availability assessed over the entire 5-h postprandial period (Fig. 3). These findings indicate that dietary protein-derived amino acid absorption is accelerated when protein is ingested in a seated compared with lying position, resulting in a greater postprandial rise in plasma essential amino acid and leucine concentrations.

The more rapid release of dietary protein-derived amino acids into the circulation following protein ingested in a seated versus lying down position may be attributed to a delay in gastric emptying rate in the lying position. Therefore, we also assessed gastric emptying rates by measuring the increase in plasma paracetamol concentrations following the combined ingestion of protein with 1.5 g paracetamol (Glerup et al. 2007; van Can et al. 2014; Holwerda et al. 2016). Peak plasma paracetamol concentrations were substantially higher in the seated versus lying down position (11.6 ± 0.5 vs. 9.3 ± 0.6 mg·L$^{-1}$, respectively) and were reached 45 min earlier when protein was ingested in the sitting position compared with the lying position (Fig. 4). In accordance, AUC analysis of plasma paracetamol concentrations over the first 60 min after protein ingestion revealed a substantially higher gastric emptying rate in the sitting position compared with lying position (Fig. 4).

Furthermore, we observed a significant positive correlation between plasma paracetamol and leucine AUC during the early postprandial period ($r = 0.60; P < 0.05$). Altogether, these data show that gastric emptying rates are 23% slower when protein is ingested in a lying body position, resulting in an attenuated postprandial rise in circulating plasma amino acid concentrations. Of course, we cannot exclude that other factors, such as changes in splanchnic blood flow, may contribute to the observed differences in postprandial protein handling following food intake in an upright sitting or supine position. These differences in postprandial amino acid availability are similar to differences observed between slowly versus more rapidly digestible proteins (Koopman et al. 2009; Pennings et al. 2011), implying that body position can strongly modulate postprandial protein handling in vivo in humans.

The present findings may be of relevance to various settings of disuse atrophy. Disuse atrophy has been partly attributed to a reduced sensitivity of the muscle protein synthetic response to the postprandial rise in plasma amino acid concentrations, and leucine in particular (Glover et al. 2008; Wall et al. 2016). In the present study, we observed that protein ingestion in a lying body position results in an attenuated rise and overall availability of plasma leucine. Therefore, feeding bedridden patients in a lying down as opposed to a normal upright sitting position may attenuate the postprandial rise in plasma amino acid concentrations, contributing to a diminished anabolic response to feeding in these patients. Proper upright body position during and after feeding may be a prerequisite to maximize postprandial muscle protein accretion and, as such, compensate for anabolic resistance.

In conclusion, protein ingestion in an upright sitting as opposed to a lying down position accelerates gastric emptying rate, accelerates dietary protein-derived amino acid absorption, and increases the postprandial rise in plasma amino acid concentrations. Therefore, an upright body position during and after feeding is recommended when aiming to optimize postprandial muscle protein accretion.
