ABSTRACT

ROSS, R. E., M. E. SALADIN, M. S. GEORGE, and C. M. GREGORY. High-Intensity Aerobic Exercise Acutely Increases Brain-derived Neurotrophic Factor. Med. Sci. Sports Exerc., Vol. 51, No. 8, pp. 1698–1709, 2019. Aerobic exercise (AEx) exerts antidepressant effects, although the neurobiological mechanisms underlying such effects are not well understood. Reduced brain-derived neurotrophic factor (BDNF) and elevated cortisol have been implicated in the pathophysiology of depression and appear to normalize with antidepressant treatment. Thus, BDNF and cortisol may serve as biological targets for developing AEx as an antidepressant treatment. **Purpose:** This study examined the effects of AEx of different intensities, on serum BDNF and cortisol in individuals with and without depression. **Methods:** Thirteen participants (10 females; age = 27.2 ± 6.9 yr; Montgomery–Åsberg Depression Rating Scale = 21.7 ± 4.7) and 13 control participants (10 females; age 27.2 ± 7.2 yr; Montgomery–Åsberg Depression Rating Scale = 0.5 ± 0.9) participated. Experimental visits consisted of 15 min of low-intensity cycling (LO) at 35% heart rate reserve, high-intensity cycling (HI) at 70% heart rate reserve, or sitting (CON). During each visit, blood samples were obtained at baseline, immediately postexercise (IP), and then every 15 min postexercise for 1 h (15P, 30P, 45P, and 60P). **Results:** There were no group differences in cortisol and BDNF. Secondary analysis revealed that BDNF increased in an intensity-dependent nature at IP, and cortisol was significantly elevated at 15P after HI. Changes in BDNF and cortisol showed significant linear relationships with changes in HR. **Conclusion:** HI AEx can elicit acute, transient increases in BDNF and cortisol in young, healthy, and physically active, nondepressed and mildly to moderately depressed individuals. This work suggests that AEx has potential to significantly affect the central nervous system function, and the magnitude of such effect may be directly driven by exercise intensity. **Key Words:** DEPRESSION, MENTAL HEALTH, NEUROPLASTICITY, NEUROBIOLOGICAL, ANTIDEPRESSANT, CORTISOL

Depression has a lifetime prevalence of 20.6% in U.S. adults and generates an economic burden of over $200 billion annually in the United States (1). Treatment options rely heavily on pharmacotherapy, although approximately one-third of patients will not achieve remission with multiple pharmacotherapeutic trials (2). Furthermore, pharmacotherapy is often associated with significant side effects, including nausea, sleep disturbances, sexual dysfunction, reduced seizure threshold, and electrocardiographic changes (3). Thus, alternative and adjunctive antidepressant therapies, with limited side effects, are needed to improve remission rates.

Depression is a multifaceted condition, and its causes are not fully understood; thus, developing novel antidepressant therapies presents a significant challenge. Psychosocial impairments, such as difficulties with relationships, and work and home responsibilities and neurobiological changes, including alterations in neurotransmitters, neurotrophins, and hormones, are all believed to contribute to depression. Aerobic exercise (AEx) has documented efficacy as a treatment for depression, and evidence suggests that AEx produces antidepressant effects when used singularly (4) or concomitant with pharmacological (5) or other nonpharmacological interventions (6). AEx may modulate mood through several mechanisms, including increased self-efficacy, increased motivation and energy, and improved psychosocial function. In addition, AEx may elicit antidepressant effects via positive neurobiological adaptations. Despite the documented benefits of AEx for improving mood and reducing depressive symptoms, our understanding of the neurobiological effects of AEx underlying these benefits remains limited.

The pathophysiology of depression involves a myriad of neurobiological alterations that manifest in reduced neuroplasticity of the brain. Neuroplasticity is the ability of the brain to adapt to internal and external stimuli through the restructuring and reorganization of neuronal connections (7).
Plasticity of the brain is critical for learning and memory processes and appears to be a vital aspect of successful depression treatment (8). Evidence suggests that reduced neuroplasticity in depression may be influenced by brain-derived neurotrophic factor (BDNF) (9) and cortisol (10). BDNF is a demonstrated mediator of neuroprotective and neuroplastic processes (11), and current evidence indicates that peripheral BDNF concentrations are reduced in depressed patients (9). Preclinical evidence suggests that serum BDNF is representative of central concentrations (12) and can cross the blood–brain barrier (13). Cortisol, a widely studied glucocorticoid, can also have powerful effects on the central nervous system (10). Cortisol is released via the hypothalamo–pituitary–adrenal (HPA) axis in response to acute psychological and physiological stress. A dysfunctional HPA axis has been implicated in depression and is evidenced by elevated resting salivary cortisol levels (14,15) and a dysregulated cortisol awakening response (15).

In addition to the cross-sectional evidence linking depression with reduced BDNF and elevated cortisol, intervention studies indicate a normalization of these pathophysiological markers with treatment (16–18). This suggests the possibility that circulating BDNF and cortisol might serve as biomarkers for treatment response and candidate targets for novel antidepressant treatments. The responses of BDNF and cortisol to AEx training interventions have been examined; however, limited and conflicting evidence exists, demonstrating the efficacy of AEx to modulate circulating BDNF and cortisol in individuals with depression (19–21). Although methodological differences, such as comparing assessments in plasma versus serum and storage and handling procedures, may have contributed to inconsistent results (16), these discrepancies may also result from variations in exercise prescription (i.e., intensity, duration, and mode) in previous longitudinal studies. Thus, examining the acute response to AEx may serve as a useful model to begin to gain a better understanding of the capacity of AEx to modulate circulating BDNF and cortisol as well as differences in response of these biomarkers between those with and without depression. Acute increases in plasma BDNF have been shown in depressed individuals in response to a single session of maximal AEx (22). In addition, acute increases in serum BDNF have been shown in healthy and depressed individuals in response to submaximal exercise, although there does not appear to be a linear relationship between exercise intensity and serum BDNF response (23–25). Further, whether inducing a stress response (measured by cortisol response) via exercise, effects of BDNF response in individuals with depression is unknown. To address these gaps in knowledge, the present study examined the neurobiological effects of different intensities of AEx in individuals with and without depression. We hypothesized that 1) compared with nondepressed control participants, depressed participants would exhibit significantly reduced BDNF, and 2) compared with nondepressed control participants, depressed participants would exhibit significantly elevated cortisol. Furthermore, we expected a dose–response relationship such that BDNF and cortisol levels would increase with exercise intensity.

METHODS

Participants

Twenty-eight individuals, 14 with depression (DEP) and 14 age- and sex-matched healthy controls (HC), participated in this study. After a brief phone screen for study eligibility, potential participants were scheduled for an in-person visit for further evaluation for eligibility and, if appropriate, to obtain informed consent. All participants were assessed with the Mini International Neuropsychiatric Interview 5.0 (MINI) (26), and the severity of depressive symptomology was assessed with the Montgomery–Åsberg Depression Rating Scale (MADRS) structured interview guide (27). The MADRS structured interview guide was selected to ensure that depression severity was assessed with a standardized battery of questions and to limit the potential of misinterpreting responses from a set of unstructured questions. Furthermore, the MADRS is widely used in depression literature, allowing for comparison with other trials. Inclusion in the DEP group was restricted to individuals meeting MINI criteria for a major depressive episode and/or who had an MADRS score >10. To control for the effect of medication dosage titration on BDNF and cortisol, participants taking antidepressant medication(s) were permitted to participate if current medication dosage had been stable for a minimum of 4 wk. Inclusion in the HC group was restricted to individuals with an MADRS score ≤6, no self-reported prior history of depression or other neuropsychiatric conditions (confirmed with the MINI), and no current, self-reported use of psychoactive drugs or medications. Further inclusion criteria were 1) ages 18–50 yr and 2) physically able and safe to exercise (as assessed by Physical Activity Readiness Questionnaire). Exclusion criteria were 1) self-reported primary diagnosis of another Axis 1 disorder; 2) self-reported secondary diagnosis of a psychotic disorder, cognitive disorder, substance-related disorder, or obsessive compulsive disorder; 3) current smoker; 4) history of seizures; 5) other diagnosed neurological or musculoskeletal disorder/injury, uncontrolled cardiovascular or metabolic disease, and electronic or metal implants; and 6) resting blood pressure ≥200 mm Hg systolic or 100 mm Hg diastolic. Participants were recruited via flyers, online and e-mail advertisements, and through an anonymous, online research recruitment tool (www.researchmatch.org).

Procedures

All procedures were approved by the Institutional Review Board of the Medical University of South Carolina and were conducted in accordance with the Declaration of Helsinki. Before performing any experimental procedures, all participants provided written informed consent. Participants attended a total of three experimental sessions. All study visits were scheduled between the hours of 12:00 and 18:00, and each participant’s experimental visit time was scheduled such that baseline assessment occurred within a 90-min window. The average time of baseline draw was 14:49 (SD = 0:56, range = 13:23–16:47) and 14:25 (SD = 1:24, range = 12:1–17:37).
for the HC and DEP groups, respectively. The purpose of conducting experimental visits in the afternoon and standardizing the baseline assessment time was to control for the potential effect of diurnal variations on BDNF and cortisol assessments. All participants were instructed to maintain their normal diet and activity habits while enrolled in the study; however, participants were asked to refrain from alcohol use the night before and from exercise the morning of each visit. Time between experimental visits ranged from 1 to 35 d. On average, the HC and the DEP groups completed experimental visits in 17 d (range = 3–55) and 19 d (range = 3–67), respectively.

**AEx**

Participants completed the prescribed exercise bouts on a stationary cycle ergometer (Ergomedic 839E; Monark, Sweden). The three experimental conditions consisted of 15 min of low-intensity cycling (LO), high-intensity cycling (HI), or sitting on the cycle ergometer (CON). Before each session, each participant was fit with a heart rate monitor (Polar, USA), and resting blood pressure was assessed. During each session, heart rate was monitored continuously, and blood pressure and RPE were assessed at baseline, every 5 min during exercise, immediately postexercise, and then 5 min postexercise. Exercise intensity was determined using the Karvonen equation. During low-intensity exercise, participants cycled to achieve a heart rate of 35% of heart rate reserve, and during high-intensity exercise, participants cycled to achieve a heart rate of 70% heart rate reserve. Participants maintained pedaling at their preferred cadence as the cycle ergometer automatically adjusted the workload to maintain the target heart rate for the session. All participants were able to achieve their target heart within the first 5 min of the exercise bout.

Participants were not informed of the order of their experimental conditions and were told about their target heart rate after baseline blood specimen collection and before beginning the exercise condition. The order of exercise conditions was randomized so that each permutation occurred only once for every six participants in each group.

**Blood Specimen Collection and Analysis**

After baseline assessments of HR, RPE, and blood pressure, a study nurse placed an intravenous catheter in a superficial forearm vein. The catheter tubing was maintained patent with an isotonic saline solution and was drained before obtaining blood specimen samples. After placement of the intravenous catheter, participants remained seated quietly until 30 min had elapsed from the time of their arrival to the laboratory. During each experimental session (HI, LO, and CON), blood samples were obtained at baseline (PRE), immediately postexercise (IP), and then every 15 min postexercise for 1 h (15P, 30P, 45P, and 60P). Immediate postexercise (IP) blood samples were taken within 1 min of exercise cessation. After exercise (or seated control), subjects remained seated on the cycle ergometer for the IP blood sample. Subjects were then seated in a chair for the duration of the experimental session and all subsequent blood samples. Blood samples were collected into 5.0-mL serum-separating tubes containing gel and clot activator (Becton Dickinson Vacutainer SST, Franklin Lakes, NJ). The South Carolina Clinical and Translational Research Institute provided a mobile nurse to perform blood specimen collection and storage during each experimental session.

Blood samples were allowed to clot upright at room temperature (RT) for at least 30 min and were then centrifuged at RT for 15 min at 1500g. The serum for each time point was then divided equally (~500 μL each) using a transfer pipette into four labeled 2.0-mL screw-cap microcentrifuge tubes (two per assay) and stored at −80°C until testing. On the day of testing, samples were removed from −80°C and allowed to come to RT for at least 1.5 h on the bench top as per the assay protocol. After plating, the samples were then moved to a −20°C freezer until they were disposed of after 30 d. Enzyme-linked immunosorbent assays were performed to determine serum BDNF (Quantikine; R&D Systems, Minneapolis, MN) and serum cortisol (IBL International, Hamburg, Germany) concentrations according to manufacturer guidelines. All samples were run in duplicate, and if the coefficient of variation exceeded 15%, samples were assayed a second time. Each sample value represents the mean of the samples assayed.

**Data Analysis**

**Statistical analyses.** Data were assessed for normality, skewness, and kurtosis. Pearson product–moment and Spearman rank-order correlations were performed on baseline cortisol, BDNF, and MADRS scores for the DEP group to examine relationships between depression severity and baseline biomarker values. Group differences on demographic and baseline blood biomarker measures were assessed using Student t-tests or Wilcoxon rank-sum tests based on distributional assessment (version 9.4; SAS, Cary, NC). The effects of group, exercise condition, and time on serum BDNF and cortisol were examined using mixed linear models. Models were initially constructed with serum BDNF or cortisol as the dependent variable and time nested within condition as the independent variable. Time was nested within condition as the effect of time was expected to be primarily driven by exercise condition. Multiple random intercepts, slopes, and covariance structures were examined, and the model that yielded the lowest Akaike information criterion was selected for modeling with fixed effects. The purpose of this initial model construction was to account for the nonindependence of repeated measures within and across multiple experimental conditions. After initial model construction, the group variable (i.e., HC vs DEP) was added as a covariate to examine the main effect of depression on serum BDNF and cortisol response. Finally, to control for demographic covariates, body mass index (BMI), medication status, age, and gender were added to the model. Main effects and interactions of covariates were examined, and Bonferroni adjustments were performed for pairwise comparisons with control for type 1 error. Significance level was set a priori at α < 0.05 for all statistical tests.
Secondary Data Analysis

In the absence of significant between-group differences, secondary within-subjects data analyses were performed. The purpose of this analysis was to determine whether BDNF and cortisol response differences existed between exercise conditions; in addition, potential relationships between changes in HR, BDNF, and cortisol were assessed across groups. A one-way ANCOVA was performed to examine the effect of condition on changes in BDNF and cortisol while controlling for group. To examine the extent to which exercise intensity explained changes in BDNF and cortisol, a simple linear regression analysis was performed using mean change in HR as the predictor variable and changes in BDNF and cortisol as the outcome variables, respectively. In addition, a correlational analysis was performed between changes in BDNF and cortisol to assess the relationship between HPA axis activation and BDNF production.

RESULTS

All 14 participants in the HC group were able to provide samples for all conditions (n = 14). During data inspection, it was found that serum BDNF values from multiple samples of one HC participant exceeded outlier values that had been previously published in HC (28). In addition, one participant from the DEP group had samples that were incorrectly labeled during processing. Because these data were not representative of this sample or contained processing errors, data from these participants were removed before statistical analysis. Thus, the final sample analysis included a total of 13 participants per group (Table 1). Because of difficulties with intravenous catheter placement, the DEP group was not able to provide a blood sample for at least one experimental condition. All subjects in the HC group were able to provide blood sample for all conditions.

Mean MADRS scores were significantly different between the HC (0.5 ± 0.9) and the DEP (21.7 ± 4.7) groups. The HC group had no reported history of depression or any other neuropsychiatric or neurological condition. All individuals in the HC group were nonsmokers and medication free. Eleven of the DEP group reported a medical diagnosis of depression, with the remaining two meeting the criteria for current major depressive episode on the MINI. The average self-reported length of current depressive episode for the DEP group was 8.2 ± 6.1 months with a range of 1 to 24 months. Nine DEP participants reported a stable dose (no changes within the previous 4 wk) of at least one psychotropic medication, and four DEP participants reported no current psychotropic medication usage. Psychotropic medications taken by participants included the following: fluoxetine (n = 3), escitalopram (n = 1), sertraline (n = 1), vilazodone (n = 1), duloxetine (n = 3), alprazolam (n = 1), memantine (n = 1), quetiapine (n = 1), mirtazapine (n = 1), topiramate (n = 1), rizatriptan (n = 1), and trazadone (n = 1).

Demographic and Baseline Biomarker Results

HC participants were sex and age (±2 yr) matched with DEP participants (Table 1). Between-group differences (HC vs DEP) at baseline included MADRS scores, BMI, weekly moderate to vigorous physical activity, and resting HR (Table 1). There were no other significant between-group differences in demographic factors. Mean resting blood pressure was not significantly different between groups, and no subjects reported having hypertension or taking antihypertensive medication. Mean baseline serum BDNF and cortisol values were not significantly different between groups.

Relationship of Depression Severity and Baseline Biomarkers

Spearman rank-order correlations indicated a significant moderate, positive correlation between MADRS and baseline cortisol (r^s32 = 0.65, P < 0.001) and no correlation between MADRS and baseline BDNF (r^s32 = −0.26, P = 0.15). There was no correlation between baseline cortisol and baseline BDNF (r^s32 = 0.09, P = 0.61).

Heart Rate and RPE Response to AEx

As a proof of concept check, between-condition differences in HR and RPE were examined. There was a main effect of condition on mean HR (F$_{2, 70} = 538.27$, P < 0.001) and mean RPE (F$_{2, 70} = 156.34$, P < 0.001). Post hoc comparisons revealed all conditions were significantly different from one another for these outcomes (all P < 0.001; Table 2). There

was a main effect of group on mean HR ($F_{1, 70} = 13.12, P < 0.001$), but there was no main effect of group on mean RPE ($F_{1, 70} = 0.28, P = 0.60$).

**Effect of Depression, Exercise, and Time on Serum BDNF and Cortisol**

**Effects on BDNF.** Serum BDNF data from all three experimental conditions were assessed to examine the effect of group, experimental condition, and time on postexercise BDNF response (Fig. 1). Covariates BMI, age, medication status, and sex were included in the model. There was no main effect of group ($F_{1, 20} = 0.12, P = 0.73$) or any covariate on BDNF. There was a significant interaction between condition and time ($F_{17, 377} = 18.77, P < 0.001$). At PRE, there was no significant difference in BDNF between conditions ($F_{2, 377} = 1.87, P = 0.15$). Bonferroni adjustments for multiple comparisons revealed that serum BDNF was significantly greater at IP in the HI compared with the LO ($t_{377} = -3.35, P = 0.003$) and CON ($t_{377} = -2.59, P = 0.027$) conditions, respectively. There was no significant difference in serum BDNF between the CON and the LO conditions ($t_{377} = 0.41, P = 1.0$) at the IP time point. BDNF at IP in the HI ($t_{377} = -8.04, P < 0.001$) and LO ($t_{377} = -3.89, P = 0.019$) conditions was significantly greater than the respective PRE values, suggesting a significant increase from baseline in both exercise conditions. The effects of AEx were transient as BDNF at the 15P time point in the HI and LO conditions was not significantly different than PRE, and there were no other between-condition differences at any other time point after exercise (all adjusted $P$ values > 0.05).

**Effects on cortisol.** Serum cortisol data from all three experimental conditions were assessed to examine the effect of group, experimental condition, and time on postexercise cortisol response (see Figure, Supplemental Digital Content 1, Absolute changes in serum cortisol, http://links.lww.com/MSS/B558). Covariates BMI, age, medication status, and sex were included in the model. There was no main effect of group ($F_{1, 20} = 1.42, P = 0.25$) or any covariate on serum cortisol. There was a significant interaction between condition and time ($F_{17, 378} = 5.25, P < 0.001$). At PRE, there was no significant difference in cortisol between conditions ($F_{2, 378} = 2.51, P = 0.08$). Bonferroni adjustments for multiple comparisons revealed several significant interactions of time and condition on cortisol. At IP, 15P, 30P, and 45P cortisol were significantly lower in the LO condition compared with the CON condition ($t_{378} = 2.91, P = 0.011; t_{378} = 2.82, P = 0.02; t_{378} = 3.08, P = 0.007; t_{378} = 2.81, P = 0.02$), respectively. By contrast,

![Figure 1](http://www.acsm-msse.org)
cortisol concentrations were higher in the HI condition compared with the CON condition during the first 30 min of recovery (15P $t_{378} = -2.46, P = 0.04; 30P$ $t_{378} = -2.60, P = 0.03$). In addition, cortisol was higher in the HI condition compared with the LO condition for the final 45 min of recovery (15P $t_{378} = -4.99, P < 0.001; 30P$ $t_{378} = -5.37, P < 0.001; 45P$ $t_{378} = -5.23, P < 0.001; 60P$ $t_{378} = -4.00, P = 0.012$). In the HI condition, cortisol was not significantly different at 60P compared with PRE ($t_{378} = -2.60, P = 1.0$), suggesting that cortisol returned to baseline levels within 1 h postexercise.

Secondary Data Analysis Results

Primary data analysis revealed no significant between-group differences in BDNF and cortisol. Data were subsequently examined for differences between conditions among the entire sample. For this analysis, change scores were calculated from PRE to IP for BDNF and from PRE to 15P for cortisol. Change scores at the IP and 15P were selected based on the significant between-condition differences observed at these time points in the primary data analysis.

Effect of Exercise Condition on BDNF and Cortisol

There was a significant effect of condition on the change in BDNF from PRE to IP ($F_{2, 67} = 21.30, P < 0.001$) while controlling for group (Fig. 2). Mean BDNF changes and 95% confidence intervals (CI) in response to HI, LO, and CON conditions were 2.60 ng·mL$^{-1}$ (95% CI = 2.04–3.16), 15.6 + 0.678 (bpm) ng·mL$^{-1}$ (95% CI = 2.04–4.44), and 0.94 ng·mL$^{-1}$ (95% CI = −0.50 to 2.38), respectively. Bonferroni adjustments revealed that change in BDNF in the HI condition was significantly greater compared with the LO ($t_{67} = -3.97, P < 0.001$) and CON conditions ($t_{67} = -6.48, P < 0.001$). In addition, the LO condition elicited a significantly greater BDNF response than the CON condition ($t_{67} = -2.54, P = 0.04$).

There was also a significant effect of condition on the change in cortisol at 15P ($F_{2, 67} = 17.01, P < 0.001$) while controlling for group. Mean cortisol changes and 95% CI in response to HI, LO, and CON conditions were 48.0 ng·mL$^{-1}$ (95% CI = 25.4–70.5), −4.67 ng·mL$^{-1}$ (95% CI = −11.7 to 2.34), and −2.50 ng·mL$^{-1}$ (95% CI = −13.4 to 8.40), respectively. The HI condition elicited a significantly greater cortisol response compared with the LO ($t_{67} = -5.17, P < 0.001$) and CON conditions ($t_{67} = -4.96, P < 0.001$). There was no significant difference in cortisol between the LO and the CON conditions ($t_{67} = 0.22, P = 1.0$). Group had no significant effect on change in IP BDNF ($F_{1, 67} = 1.58, P = 0.22$) and 15P cortisol ($F_{1, 67} = 0.04, P = 0.84$).

Relationship of change in HR with change in BDNF and cortisol. A simple linear regression was performed to examine change in postexercise BDNF and change in HR. A significant relationship was found ($F_{1, 69} = 34.1, P < 0.001, R^2 = 0.33$), with change in BDNF equal to 0.663 + 0.071 (bpm) ng·mL$^{-1}$ (Fig. 3). Thus, at the IP time point, BDNF increased 0.71 ng·mL$^{-1}$ for every increase of 10 bpm in HR from baseline. Similarly, we also examined change in cortisol based on HR response. A significant relationship was found ($F_{1, 69} = 25.9, P < 0.001, R^2 = 0.27$) as change in cortisol was equal to −15.6 + 0.678 (bpm) ng·mL$^{-1}$. Thus, 15P cortisol increased 6.78 ng·mL$^{-1}$ for every increase of 10 bpm in HR from baseline.

Relationship of change in BDNF and change in cortisol. A Pearson product–moment correlation was performed to assess the association between the changes in BDNF and cortisol after exercise. There was a significant, small correlation between change in IP BDNF and change in IP cortisol

![Figure 2](image-url)
($r = 0.29, n = 71, P = 0.02$) and a significant, small correlation between change in IP BDNF and change in 15P cortisol ($r = 0.39, n = 71, P < 0.001$) (Fig. 4).

**DISCUSSION**

The primary purpose of this study was to examine the acute neurobiological responses to AEx of different intensities in individuals with and without depression. To our knowledge, this is the first investigation to examine the acute effects of different intensities of AEx on BDNF and cortisol responses in depressed versus nondepressed (HC) individuals. Contrary to our expectation, there were no group differences in either serum BDNF or cortisol levels. Our finding that BDNF response did not differ between groups is consistent with the previous work by Gustafsson and colleagues (22) who reported no significant effect of group in BDNF response to maximal AEx in 18 HC and 18 DEP subjects. Furthermore, the lack of between-group differences in cortisol is consistent with Kiive et al. (29), who found no differences in cortisol response to maximal AEx in 22 HC and 24 DEP subjects. It should be noted that conflicting work by Krogh et al. (30) indicated a significant effect of...
group on cortisol response to maximal AEx in 44 HC and 137 DEP subjects. However, it is possible that the conflicting reports in the literature may be driven by the composition of samples as Kiive et al. (2004) studied an all-male sample whereas Krogh et al. (2010) studied a sample that was 75.1% female. Females with depression have been shown to have greater resting cortisol concentrations compared with nondepressed females (31). In addition, compared with males, females have demonstrated an exaggerated cortisol response to dexamethasone/corticotropin-releasing factor stimulation testing (32). Thus, sex differences in resting and exercise stimulated cortisol responses are a plausible explanation for the conflicting results in the literature, although our results did not indicate that sex significantly affected BDNF or cortisol.

Several aspects of this sample should be considered when interpreting the lack of between-group differences in BDNF found in this trial. There was a small effect size ($d = 0.29$) when compared with HC on resting BDNF, but we were insufficiently powered to detect this observed effect. A recent meta-analysis assessed the effect of depression on resting serum BDNF compared with nondepressed controls (33). In this study, Molendijk and colleagues (33) reported a medium, negative effect of antidepressant-free depression ($d = -0.47$) on resting BDNF concentrations when compared with HC. However, there was no difference in resting BDNF concentrations between those treated with antidepressants ($d = 0.07$) and HC. Considering that ~70% of our DEP group were on a stable dose of antidepressant medication, it is possible that BDNF levels were normalized by treatment, thereby explaining the lack of difference in resting and post-AEx BDNF. Antidepressant treatment via selective serotonin reuptake inhibitor (SSRI), which was reported by all but one medicated participant (SSRI $n = 8$; serotonin and norepinephrine reuptake inhibitor $n = 1$), has been shown to increase serum BDNF in depressed patients to a level that is comparable with HC (34). Preclinical evidence indicates that SSRI treatment stimulates endogenous BDNF production in cortical glial cells through increases in BDNF mRNA expression (35). Moreover, SSRI treatment increases the activation of BDNF’s cellular receptor, tropomyosin receptor kinase B, which may enhance further neurotrophin signaling (36). To our surprise, on average, our DEP group was moderately highly physically active. Lastly, although our DEP sample may have had less severe depressive symptoms and were relatively younger than in previous studies (22,23), neither depressive symptom severity nor age was associated with resting BDNF (33). Relatedly, Meyer et al. (23) reported that change in BDNF after a single session of AEx was not related to short-term changes in depressed mood, and previous work indicates that acute BDNF response to exercise can occur across the life span (37).

There was no effect of depression on resting cortisol in our sample. Meta-analytic research comparing adults with and without depression indicate a medium effect ($d = 0.60$) of depression on resting cortisol, although this effect size was reduced ($d = 0.33$) when stricter methodological standards were used (38). Steller and Miller (38) also reported significantly increased cortisol in older participants as well as inpatients and more severely depressed individuals. Our younger, mild to moderately depressed cohort was likely a primary contributor to the lack of between-group differences in resting cortisol. In response to AEx, both groups demonstrated similar cortisol responses in all three experimental conditions. In contrast with previous literature (39), the HC group seemingly demonstrated a normal HPA axis response to AEx. Thus, it appears that our DEP group did not exhibit an abnormal stress response to AEx. Interestingly, females with depression have previously been shown to have a blunted cortisol response to psychosocial stressors compared with HC while males demonstrate an exaggerated response (40). Although our limited sample prevents us from making comparisons across sex, our sample of primarily females did not appear to demonstrate such a response. In fact, during the most stressful condition (HI), the change in the cortisol concentration of DEP females at 15P ($60.5 ± 43.6 \text{ng·mL}^{-1}$) was comparable with that of the HC females ($45.5 ± 66.0 \text{ng·mL}^{-1}$). This may suggest that HPA axis dysfunction may not have been present in our DEP sample or that the mild to moderate nature of depression in this group did not significantly affect the HPA axis function. Another possibility is that depressed individuals who perform regular moderate to vigorous activity may maintain HPA axis function and stress reactivity (41). Therefore, the physical activity status of our DEP group may serve as a protective mechanism contributing to improved cortisol response to AEx.

Secondary analyses revealed that the sample, as a whole, demonstrated an intensity-dependent change in BDNF immediately post-AEx. Cortisol was not affected in an intensity-dependent manner; however, the HI condition elicited a significant increase at the 15P time point. Heart rate change was a significant predictor of both changes in IP BDNF and 15P cortisol, explaining 33% and 27% of the variance in each biomarker, respectively. In addition, changes in BDNF and cortisol were positively associated with one another, although this relationship is likely driven by heart rate change or exercise intensity.

**Effects of exercise intensity on BDNF.** Our results indicated that exercise intensity appears to be an important feature in the ability of AEx to augment circulating BDNF. These results are previously corroborated by several studies examining acute BDNF responses to AEx in young, nondepressed cohorts (25,39,42). For example, Hötting and colleagues (25) examined the effect of exercise intensity on BDNF in young, healthy adults who cycled for a total of 30 min at an intensity similar to that used in our study. Consistent with our findings, their results indicated that the high-intensity (145 bpm; ~80% $HR_{\text{max}}$) cycling group demonstrated a significantly greater BDNF response compared with the low-intensity (99 bpm; <57% $HR_{\text{max}}$) and control groups, immediately after exercise. Interestingly, their low-intensity group did not demonstrate a significant change in BDNF compared with the nonexercise control group. Rojas Vega et al. (39) also reported similar results, finding no significant changes in BDNF after a 10-min moderate-intensity warm-up (~128 bpm), but significant increases after a maximal capacity (~189 bpm) cycling test. Ferris and colleagues (42) also reported an intensity-dependent change in BDNF after maximal
exercise, and 30 min of exercise at +10% and −20% of ventilatory threshold (VT). Maximal (−175 bpm) and +10% VT (−150 bpm) cycling both elicited significant increases in BDNF, whereas −20% VT (−122 bpm) failed to induce a significant change in BDNF. Our results combined with previous findings suggest that a single session of AEx can increase peripheral BDNF and that this increase occurs in an intensity-dependent manner, resulting in linear relationship between heart rate and BDNF.

In addition, our project, along with others, has demonstrated that a single session of AEx can increase peripheral BDNF for a brief time before it returns to preexercise concentrations. The transient nature of this response is not fully understood but is potentially important to understanding the long-term effects of AEx on BDNF response. The ability of exercise to modulate BDNF expression may be stimulated by the contraction of skeletal muscle (43). Matthews and colleagues (43) examined the effects of 2 h of stationary cycling at 60% VO2max on serum BDNF and skeletal muscle BDNF mRNA in eight young, healthy, untrained men. Serum BDNF and muscle BDNF mRNA via muscle biopsies were assessed at baseline, immediately after the exercise bout, and then at 3, 5, 8, 24, 48, and 72 h after exercise. Results indicated that serum BDNF was significantly higher immediately after exercise and then returned to baseline values for all time points afterward. By contrast, BDNF mRNA expression peaked at 5 h postexercise and remained above baseline levels up to 72 h postexercise. Furthermore, muscle biopsies revealed a 50% increase in BDNF protein levels relative to baseline at 24 h postexercise. Thus, it appears that although circulating serum BDNF returns to baseline levels in a short period, the expression of BDNF in target tissues may remain elevated for 24–72 h after high-intensity exercise. This evidence suggests that although circulating BDNF undergoes rapid up- and down-regulation in response to AEx, the overall effects of a single session of AEx on BDNF expression may last several hours to several days postexercise.

Demonstrating the ability of AEx to positively modulate BDNF is an important step in the continued pursuit of AEx as a viable option for antidepressant treatment. Previous work examining the effects of exercise on BDNF has established the potential neurobiological underpinnings of the antidepressant response to exercise as elevated BDNF has been shown to be a strong predictor of remission after AEx treatment and reduced BDNF, a strong predictor of nonresponse to AEx treatment for depression (44). Considering that BDNF has significant influence on neuroplasticity, AEx could have the potential to be used clinically for depression as well as other neuropsychiatric or neurological conditions in which neuroplasticity may be compromised. Based on the existing evidence, it appears that high-intensity exercise is the most likely candidate to modulate BDNF expression.

**Effects of exercise intensity on cortisol.** A physical stressor, in this study high-intensity AEx, demonstrated a predictable cortisol response in our sample. Our results indicated that high-intensity AEx elicited a significant increase in cortisol at 15P, which is consistent with previous work examining the acute glucocorticoid responses to exercise (39). The delay in cortisol response to high-AEx is a result of the activation of the HPA axis and the adrenal glands and cortisol, which are working downstream from the pituitary gland and adrenocorticotropic hormone (ACTH). Seminal work by Luger and colleagues (45) showed that ACTH peaked during AEx at intensities of 70% and 90% of VO2max in young, HC subjects. Cortisol peaks occurred during the recovery period, which coincided with a reduction in ACTH. In addition, the magnitude of change in ACTH and cortisol was intensity dependent, with near maximal AEx eliciting the greatest ACTH and subsequent cortisol responses. The temporal relationship of ACTH and cortisol in these conditions also suggests that the negative feedback mechanisms by which the HPA axis is regulated were normal functioning as ACTH production reduced as cortisol concentrations increased.

The high-intensity condition in the current study resulted in the greatest cortisol response and ultimately served as a test of HPA axis response to stress. The time course of the cortisol response appeared to be similar to previously published work, although we did not assess corticotropin-releasing hormone or ACTH to get a full picture of HPA axis function. Acute bouts of AEx, specifically of high intensity, may serve as stress challenges to examine differences in HPA axis function between HC and depressed individuals, and perhaps even various subtypes of depression. Assessing the temporal relationships of corticotropin-releasing hormone, ACTH, and cortisol are important in elucidating the function of HPA axis in response to acute exercise in depressed cohorts and the potential adaptations that may occur with chronic exercise. It is possible that AEx may benefit those with depression through improved HPA axis regulation that has been shown in nondepressed individuals with higher aerobic fitness (46). Thus, understanding the acute and chronic responses of the HPA axis may provide valuable information regarding the neurobiological benefits of AEx in depression.

**Relationship of cortisol and BDNF.** Preclinical evidence suggests that glucocorticoids (i.e., cortisol) regulate BDNF mRNA expression (47) and chronic exposure to glucocorticoids reduces BDNF through the disruption of the BDNF signaling pathway (48). In humans, Ambrus and colleagues (49) reported an inverse relationship between serum cortisol and plasma BDNF in female suicide attempters. In addition, they reported a positive relationship between concentration difficulties and serum cortisol and lower plasma BDNF. Further, Issa and colleagues (50) reported inverse relationships between prefrontal cortex cortisol and BDNF and cerebrospinal fluid cortisol and BDNF in postmortem schizophrenia subjects. The evidence cannot directly indicate that reduced BDNF and elevated cortisol are the sole cause of depression or other neuropsychiatric conditions; however, it does appear, at least from preclinical models, that cortisol can affect BDNF regulation, and both may serve as potential therapeutic treatment targets.

Interestingly, BDNF appears to increase with the remission of depressive symptoms and/or pharmacological antidepressant...
HIGH-INTENSITY AEROBIC EXERCISE ELEVATES BDNF

CONCLUSIONS

In light of the findings of this study, it appears that high-intensity AEx can elicit acute, transient increases in BDNF and cortisol in young, healthy, and physically active, nondepressed, and mild to moderately depressed individuals. However, given the small sample size and the unique characteristics of the depression group, caution must be taken in interpreting these results to a larger population. Through the assessment of neurobiological markers, this work suggests that AEx has the potential to significantly affect the central nervous system function and that the magnitude of such effect may be directly driven by intensity of exercise. Establishing exercise as a neuromodulatory treatment option can be useful to the fields of neuropsychiatry and neurorehabilitation and further work should focus on the mechanistic underpinnings and the overall magnitude of effect in treatment studies. Questions remain regarding the ability of AEx to predictably modulate BDNF and cortisol in moderate to severely depressed and treatment-resistant patients. In addition, the benefit of adjunctive AEx to pharmacological antidepressant treatment is established; however, questions remain regarding its role in combination with less commonly prescribed treatments such as rTMS and ECT.

The authors thank a dedicated group of study participants for their time and effort that made this study possible. A special thank you to Campbell Long and Kristen Buchanan, BSN, RN, for their assistance with data acquisition and processing. This project was supported by funding from the National Institute of General Medical Sciences under treatment (33). Also, after a 3-month yoga-only program, subjects demonstrated a significant inverse relationship between change in serum cortisol and change in serum BDNF, which would suggest that chronic exercise may reduce cortisol and increase BDNF (17). However, the relationship of these markers in response to either chronic or acute exercise is not well studied. In this current study, changes in BDNF and cortisol demonstrated weak, although significant, relationships with another. In addition, change in IP BDNF demonstrated a stronger relationship with 15P cortisol ($r = 0.39$) than with IP Cortisol ($r = 0.29$), suggesting that peak changes in BDNF may precede peak changes in cortisol. Based on these results, it would appear that a stimulus potent enough to evoke a cortisol response would be needed to acutely stimulate BDNF. However, we are unable to conclude on whether cortisol regulation would improve over the course of an exercise training program.

Both BDNF and cortisol are of particular importance to neuropsychiatric and neurologically compromised populations because of their potential effect on neuroplasticity (51, 52). Given the sizeable amount of literature examining these biomarkers, the coupling of changes in BDNF and cortisol warrants further investigation. Examining the relationship of these biomarkers in response to acute and chronic treatment of depression may help in the advancement of treatment paradigms as well as in identifying potential predictors of treatment response.

Limitations. Our study contained several limitations that should be considered when interpreting the results. First, our participants with depression were community-dwelling individuals with mild to moderate depression. Thus, the current results cannot be extrapolated to inpatient or more severely depressed patients. In addition, our recruitment materials specifically stated that exercise was involved in this project. As a result, our study likely is at risk of selection bias of individuals that were more physically active or fit. We did not match our samples for activity level, which resulted in the HC group reporting more moderate to vigorous physical activity than the DEP group, although overall activity was not significantly different between groups. Our sample also contained a mix of males and females, and although they were sex matched, there are likely sex-specific neurobiological differences for which we were unable to decipher in this sample. Next, although all participants were either taking a stable dose or were not currently using antidepressant medication, it is possible that medications may have normalized biomarker responses in those taking medication, thus influencing group responses. In addition, we did not assess our sample for the presence of the BDNF Val66Met polymorphism. Although we are unable to account for the potential influence of this genetic variation on the BDNF response to exercise, recent work suggests that the presence of this polymorphism does not attenuate BDNF response to high-intensity exercise (53). In humans, peripheral measures of BDNF may not be representative of central concentrations, and caution should be taken when interpreting blood-based measures of BDNF as such. We did not correct BDNF and cortisol for potential plasma volume changes in response to exercise and may have overestimated their concentrations. However, previous work shows that when correcting for plasma volume changes, BDNF and cortisol remain significantly elevated after exercise (54, 55). Because all sessions took place in the afternoon, participants were permitted to attend experimental sessions in a nonfasted state. As a result, we cannot exclude that a preexperimental meal may have influenced either BDNF or cortisol results. Lastly, our sample was young and otherwise without comorbid conditions; thus, our results cannot be generalized to older or elderly populations or those with multiple neuropsychiatric or other health conditions.

Future directions. Although this work shows that a single session of AEx can acutely stimulate BDNF production in young, healthy, and physically active, nondepressed, and mild to moderately depressed individuals, more work is needed in this area. Future work should be aimed at studying the ability of AEx to stimulate BDNF in sedentary, more severely depressed, and medication-free individuals as well as other neuropsychiatric and neurologic cohorts. Whether long-term exercise training can enhance resting levels of BDNF in depressed cohorts and how this may correspond with antidepressant response remains unclear. Examining the relationship between treatment response and BDNF will be useful in identifying the characteristics of responders to AEx treatment. Lastly, identifying exercise training parameters (i.e., mode, frequency, intensity, and time) that elicit optimal psychobiological responses will be important in further establishing exercise as a clinically viable treatment for depression.
